## Associations in systems genetics

2

Systems genetics is all about associations between different datasets. It's critical, then, that the sample labels are correct for all data sets. As projects become larger and involve more groups of scientists, there's a greater chance for the introduction of errors in the sample labels.

Sample duplicates, mixtures, and mix-ups will all weaken associations and so reduce the quality of the study results.

On the other hand, with high-throughput genomic phenotypes, there is often the opportunity to both identify sample mix-ups and correct them.

## Sample mix-ups

Broman et al. (2015) doi:10.1534/g3.115.019778

3

Here's an example of a set of mix-ups in the DNA samples for a project. In a mouse intercross with about 500 samples, there were nearly 20% mix-ups. The dots indicate that the correct sample was in the correct place. The arrows point from where a sample should have been to where it was actually found.

In this project, we had gene expression microarray data from six different tissues; that allowed us to identify and correct these errors.

## More sample mix-ups

Broman et al. (2015) doi:10.1534/g3.115.019778

4

The mRNA samples had mix-ups, too. There were errors in each of the six tissues.

## Westra et al. (2011)

**Table 2.** *Cis*-eQTL mapping and sample mix-up identification results

Stud	Population	Sample-size	Initial <i>cis</i> -eQTLs	Mix-ups detected <sup>a</sup> <i>n</i> (%)	Sample-size after correction <i>n</i> (%)	<i>cis</i> -eQTLs after correction <i>n</i> (%)

Westra et al. (2011) doi:10.1093/bioinformatics/btr323

5

Westra et al. (2011) was among the first to identify this potential problem and suggest a formal solution. They applied their approach to a number of public data sets and identified problems in most of them, including a study with 20% mix-ups.

# Outline

- ▶ Sample duplicates
- ▶ Sex verification
- ▶ mRNA  $\leftrightarrow$  protein
- ▶ mRNA  $\leftrightarrow$  DNA
- ▶ protein  $\leftrightarrow$  DNA

If you have high-throughput, low-level phenotypes, you should at least attempt to identify potential sample mix-ups. My goal in this talk is to make it clear how to do this, to help ensure that this becomes a routine part of the data cleaning procedures in eQTL analyses.

But first

## Missing Data

7

Before you do anything, you should look at the amount of missing data, as this is often an important indication of sample quality.

## Percent missing genotypes

8

Here's a diversity outbred mouse project with 500 mice. Five samples had  $> 25\%$  missing data and almost surely need to be omitted. A couple of samples have around 10% missing data and might be recoverable but are still worth watching.

Note that I'll be using a variety of data in this talk, but I won't be explaining where it's from. But I thank my collaborators for the data.

# Sample duplicates

9

The next thing to look for is sample duplicates. Are there pairs of individuals with too-similar genotypes?

These are pretty common. I don't know anything about monozygotic twins among mice, but we've always assumed that these are cases of sample duplication or contamination.

## Percent matching genotypes

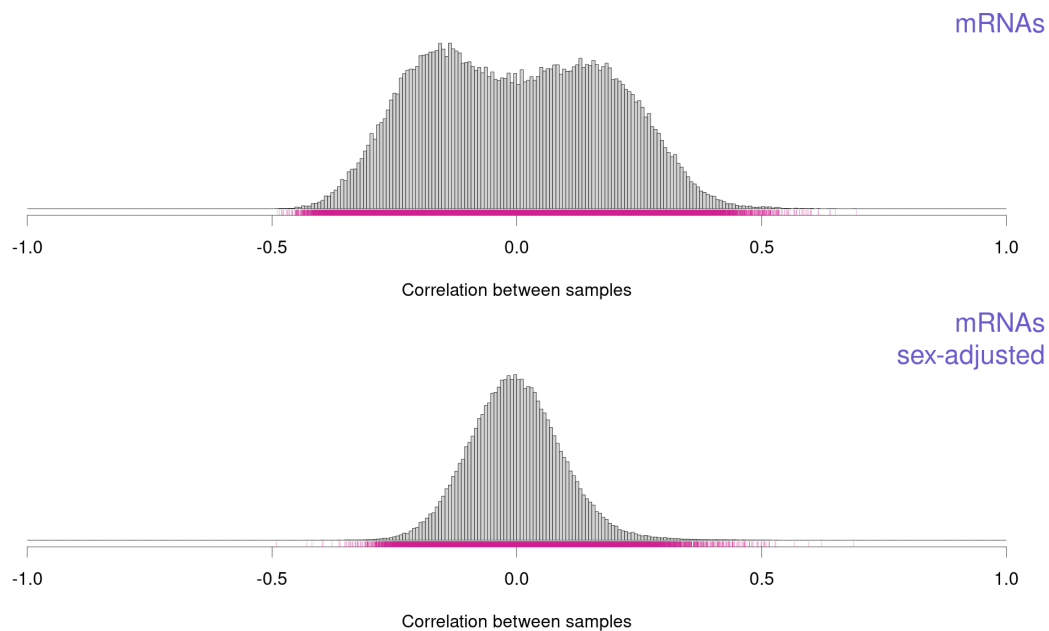

10

It's simple to look for duplicate DNA samples: just calculate the proportion of matching genotypes for each pair of samples, and look for pairs that have very similar data.

Here, we see no close matches. There's a group with rather low sharing, which are due to a couple of bad DNA samples, plus a group with somewhat above-normal sharing, which are likely siblings (these are again diversity outbred mice).

This technique only works well for organisms with a lot of chromosomes. It would be hard to do this in *Drosophila*, because the variation in the “just by chance” sharing would be really high and cover the full rather 0–100%.

# Correlation between mRNA samples

11

It seems like you should be able to do the same thing with mRNA or protein samples: just look at the correlation between samples, or perhaps the RMS difference. But I've not had much success finding duplicate samples this way. You maybe need to exclude genes that appear to not be expressed (and so are just noise).

These are histograms of the correlation between mRNA expression samples. The two sexes are anti-correlated. The lower histogram is for correlation between measurements after controlling for sex.

# Correlation between protein samples

12

This is similar as the last slide, but with mass-spec-based protein measurements. The anti-correlation between sexes is not as strong but still present.

# Sex verification

13

One way to identify sample mislabelings is by comparing the annotated sex to what you can infer from the genotypes or expression data.

## X and Y genotype dosage

14

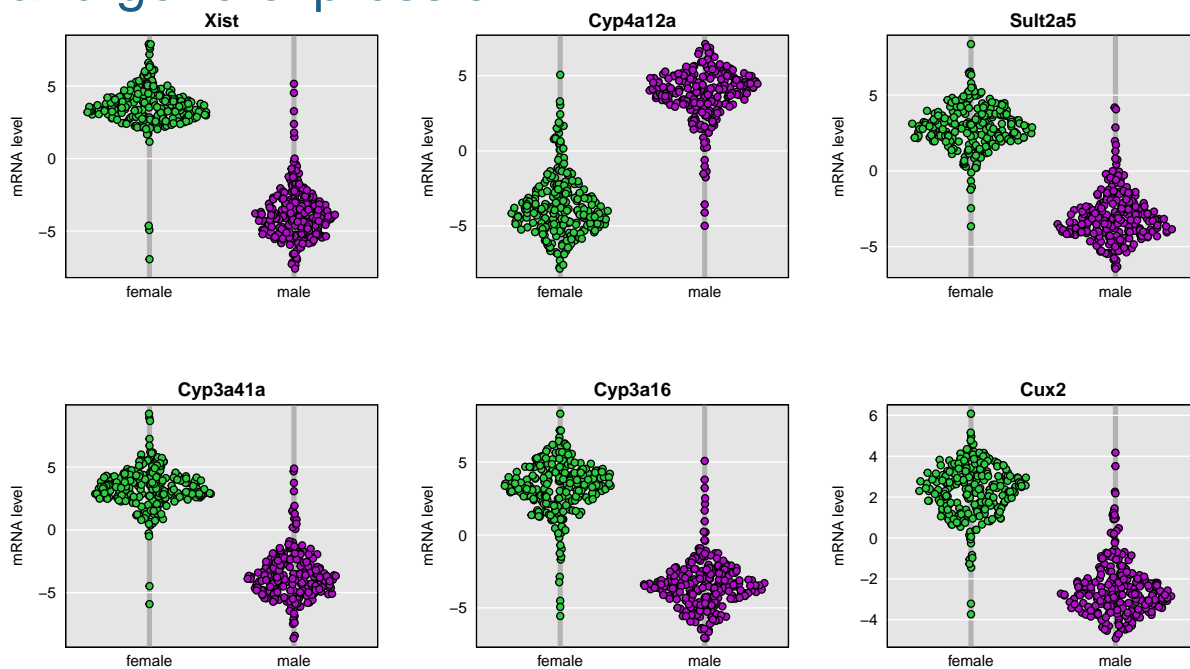

Historically, I would look at heterozygosity on the X chromosome to verify sex. But even better, for verifying sex in the genotype data, is to look at the dosage of X and Y chromosome markers (average intensity for microarray-based genotypes, or frequency of mapped reads for sequencing-based genotypes).

The x-axis is average intensity of SNPs on the X chromosome; the y-axis is average intensity of SNPs on the Y chromosome.

The green ball in the lower-right are females with two X chromosomes and no Y. The purple ball in the upper-left are males with one X and one Y. The points in the lower-left are maybe XO females.

We are looking for females in the upper-left (and there is one such) or males in the lower-right.

## Sex and gene expression

15

We should be able to do the same sort of thing, to verify the sex of the mRNA samples.

We could think hard about genes that should show a big sex difference (for example, Xist), or we could just do t-tests to identify a set of genes that have big sex differences. These are the top six genes, in terms of sex difference in expression. Of course, Xist is the first.

We could choose the top say 100 genes and use them to form a classifier for sex from gene expression. We want a method that can handle some misclassified samples.

## Sex and gene expression

16

What I ended up doing was just pick the top 100 genes and then calculate the mean in males and females, and then for each sample, look at the RMS difference from the male means and from the female means. This is a plot of those.

Most of the samples have well-differentiated sex by this approach, but there are a bunch of samples in the middle, maybe due to batch differences that I've not accounted for?

Anyway, while there are a number of samples in the middle that are unclear, there's also a set of males that look like females and one female that looks like male.

## Sex and proteins

17

Protein levels also show big sex differences, so we can do the same thing again with proteins.

## Sex and proteins

18

I did the same thing as with the mRNA data: pick the top 100 proteins by their sex difference. Calculate the average for males and for females, and then take the RMS difference for each sample from the male means and the female means.

For this particular data set, there are a number of females deep within the males.

mRNA  $\leftrightarrow$  protein

DNA  $\leftrightarrow$  mRNA

DNA  $\leftrightarrow$  protein
